FIELD OF THE INVENTION

This invention relates generally to colonoscopy techniques and more particularly to a system for processing the image of a bowel to remove bowel contents from the image and for detecting polyps in the digital image.

BACKGROUND OF THE INVENTION

As is known in the art, a colonoscopy refers to a medical procedure for examining a colon to detect abnormalities such as polyps, tumors or inflammatory processes in the anatomy of the colon. The colonoscopy is a procedure which consists of a direct endoscopic examination of the colon with a flexible tubular structure known as a colonoscope which has fiber optic or video recording capabilities at one end thereof. The colonoscope is inserted through the patient's anus and directed along the length of the colon, thereby permitting direct endoscopic visualization of colon polyps and tumors and in some cases, providing a capability for endoscopic biopsy and polyp removal. Although colonoscopy provides a precise means of colon examination, it is time-consuming, expensive to perform, and requires great care and skill by the examiner. And, the procedure also requires thorough patient preparation including ingestion of purgatives and enemas, and usually a moderate anesthesia. Moreover, since colonoscopy is an invasive procedure, there is a significant risk of injury to the colon and the possibility of colon perforation and peritonitis, which can be fatal.

To overcome these drawbacks, the virtual colonoscopy was conceived. A virtual colonoscopy makes use of images generated by computed tomography (CT) imaging systems (also referred to as computer assisted tomography (CAT) imaging systems). In a CT (or CAT) imaging system, a computer is used to produce an image of cross-sections of regions of the 5 human body by using measure attenuation of X-rays through a cross-section of the body. In a virtual colonoscopy, the CT imaging system generates two-dimensional images of the inside of an intestine. A series of such two-dimensional images can be combined to provide a three-dimensional image of the colon. While this approach does not require insertion of an endoscope into a patient and thus avoids the risk of injury to the colon and the possibility of colon 10 perforation and peritonitis, the approach still requires thorough patient preparation including purgatives and enemas. Generally, the patient must stop eating and purge the bowel by ingesting (typically by drinking) a relatively large amount of a purgative. Another problem with the virtual colonoscopy approach is that, the accuracy of examinations and diagnosis using virtual colonoscopy techniques is not as accurate as is desired. This is due, at least in part, to the relatively large number of images the examiner (e.g. a doctor) must examine to determine if a polyp, tumor or an abnormality exists in the colon.

It would, therefore, be desirable to provide a virtual colonoscopy technique which removes the need for bowel cleansing. It would also be desirable to provide a virtual colonoscopy technique which removes the need for thorough patient preparation.

It would further be desirable to provide a technique which increases the accuracy of examinations and diagnosis using virtual colonoscopy. It would be further desirable to provide a technique which reduces the number of images an examiner (e.g. a doctor) must examine to 25 determine if a polyp, tumor or an abnormality exists in the colon. It would be further desirable to provide a technique for automatic detection of polyps, tumors or other abnormalities in the colon.

#### SUMMARY OF THE INVENTION

In accordance with the present invention, an apparatus for performing a virtual 30 colonoscopy includes a system for generating digital images, a storage device for storing the

digital images, a digital bowel subtraction processor coupled to receive images of a colon from the storage device and for processing the received digital images of the colon to digitally remove the contents of the colon from the image. With this particular arrangement, a system which provides accurate results without the need for thorough patient preparation (e.g. without the need for bowel cleansing) is provided. The digital bowel subtraction processor (DBSP) receives image data from the image database and processes the image data to digitally remove the contents of the bowel from the digital image. The DBSP can then store the image back into the image database. Since the DBSP digitally subtracts the contents of the bowel, the patient undergoing the virtual colonoscopy need not purge the bowel in the conventional manner which is known to be 10 unpleasant to the patient. The system can further include an automated polyp detection processor coupled to receive images of a colon from the storage device and for processing the received digital images of the colon to detect polyps in the colon image.

The automated polyp detection processor (APDP) receives image data from the image storage device (which may be provided as an image database, for example) and processes the image data to detect and /or identify polyps, tumors, inflammatory processes, or other irregularities in the anatomy of the colon. The APDP can thus pre-screen each image in the database such that an examiner (e.g. a doctor) need not examine every image but rather can focus attention on a subset of the images possibly having polyps or other irregularities. Since the CT system generates a relatively large number of images for each patient undergoing the virtual colonoscopy, the examiner is allowed more time to focus on those images in which it is most likely to detect a polyp or other irregularity in the colon. The APDP can process images which have been generated using either conventional virtual colonoscopy techniques (e.g. techniques in which the patient purges the bowel prior to the CT scan) or the APDP can process images in 25 which the bowel contents have been digitally subtracted (e.g. images which have been generated by DBSP).

In accordance with a still further aspect of the present invention a technique for digital bowel subtraction includes the steps of applying a threshold function to the image data and 30 selecting all image elements above the threshold for further processing, applying a gradient to the

original image to identify “shoulder regions” and then performing an image dilation step on the shoulder region (i.e. an expansion is performed on selected pixels in the shoulder region). The bowel contents are digitally subtracted based on the gradient analysis. Thus, after selecting and dilating the gradient the subtraction of the bowel contents is performed. Mathematically this can  
5 be represented as Subtracted Image Values  $\approx$  Original Image Values - (Threshold Values + Gradient Values).

In accordance with a still further aspect of the present invention a technique for digital bowel subtraction includes the steps of scanning across a matrix of digital values which represents  
10 an image, identifying regions corresponding to regions of a colon, identifying regions corresponding to regions of air and bowel contents in the colon and subtracting one region from the other to provide an image with the bowel contents removed. With this technique, a raster based searching method is provided. By scanning an image in a raster pattern and applying threshold values in a predetermined logic sequence, pixels representing air which are located proximate pixels representing bowel wall are found. Once a region corresponding to a boundary region between bowel contents and a bowel wall is found, the pixels which represent the bowel contents can be subtracted from the image. In one embodiment, the pixels representing the bowel contents are subtracted from the image by setting the values of the pixels to value corresponding to air.

In accordance with a still further aspect of the present invention a technique for automatic polyp detection includes the steps of generating a polyp template by obtaining a CT image which includes a polyp and excising the polyp from the image and using the excised polyp image as the template. Next, a portion of a CT image is selected and a polyp identification function is applied  
25 to the selected portion of the CT image. Next, a correlation is performed between the output of the identification function and the image. With this particular arrangement, a technique for automated polyp detection is provided.

In accordance with a still further aspect of the present invention, a second technique for  
30 automatic polyp detection includes the steps of moving a test element along a boundary of a

bowel. When the test element is rolled around the bowel perimeter, the changes in direction of the test element are detected as the changes occur. The features of the bowel perimeter are classified based upon the path of the test element. Thus, an advance knowledge of the geometric characteristic of the polyp or other irregularity being detected is required. The process of 5 classifying the features of the bowel are accomplished by marking three points where turns exist. The points are selected by looking at the changes in slope (e.g. the derivative). Next the distances between the marked points are computed and the ratios between the distances are used to identify bowel features or characteristics of the bowel. In one embodiment, the test element is provided having a circular shape and thus is referred to as a virtual rolling ball, a virtual ball, or more simply 10 a ball.

In accordance with a still further aspect of the present invention, a third technique for automatic detection of structures, including but not limited to polyps, includes the steps of applying a template to a segmented bowel image corresponding to the bowel perimeter and computing the distances between points on the template perimeter and the perimeter bowel points present within a window. Next, a determination is made as to whether the distances are equal. When the template becomes centered within a lesion, then the distances from one or more points on the template to bowel boundary points of the structure (e.g. a lesion)become substantially equal. The distances may be measured from a number of points on the template. For example, a center point of the template, perimeter points of the template or other points on the template may be used. The particular points to use on the template are selected in accordance with a variety of factors including but not limited to the template shape and the physical characteristics (e.g. shape) of structure being detected. To make a determination of when the computed distances are substantially equal, a standard deviation of a group of those distances can be computed. The 25 template location at which the standard deviation values approach a minimum value corresponds to a location at which a structure having a shape similar to the template shape exists. Alternatively, an average distance from a point on the template (e.g. a template center point) to the perimeter of the boundary structure (e.g. a bowel wall) can be computed. In this case, a location at which a structure having a shape similar to the template shape exists can be found 30 when the average distance from the point on the template to the boundary structure perimeter

points reaches a minimum value. The above process can be carried out in one plane or in three orthogonal planes. The point where the standard deviation of a group of those distances approaches a minimum value is the point which should be marked as a center of a suspected lesion. In the case where the technique is run in three orthogonal planes, those lesions that were 5 tagged in 2 of 3 or 3 of 3 planes can be finally tagged as suspicious regions. This technique can thus be used to distinguish a fold from a polyp. With this particular arrangement, a technique which searches for patterns of distance is provided. The technique is thus relatively computationally expensive but it is also relatively rigorous. One advantage of this technique is that does not matter how large the template is relative to the polyp so one scanning works for all 10 lesions.

## BRIEF DESCRIPTION OF THE DRAWINGS

The foregoing features of the invention, as well as the invention itself may be more fully understood from the following detailed description of the drawings, in which:

FIG. 1 is a block diagram of a system for digital bowel subtraction and automatic polyp detection;

FIGS. 1A – 1D a series of views illustrating a digital image of a bowel before and after processing via a digital bowel subtraction processor;

FIG. 2 is a flow diagram showing the steps in a virtual colonoscopy performed using digital bowel subtraction;

25 FIG. 3 is a flow diagram showing the steps in a first method for performing digital bowel  
subtraction;

FIG. 4 is a diagram showing the volume averaging area in a portion of a colon;

FIGs. 4A – 4C are plots of pixel values vs. pixel locations in the formation of a bowel wall/air boundary;

5 FIG. 5 is a flow diagram showing the steps in a second method for performing digital bowel subtraction;

FIGs. 5A is diagrammatic view of an image of the type generated by a CT system and having a local window disposed thereover;

10 FIG. 5B is a portion of the image shown in FIG. 5A taken along lines 5B-5B showing a polyp obscured by bowel contents;

FIG. 5C is a portion of the image shown in FIG. 5A taken along lines 5B-5B after the digital bowel subtraction process and in which the polyp is clearly visible;

Fig. 5 D is a pixel analysis map;

FIG. 6 is a flow diagram showing the steps to digital subtract bowel contents in a region between opacified and non-opacified material in a bowel;

FIGs. 6A and 6B are a series of plots illustrating the threshold process;

FIG. 7 is a flow diagram showing the steps of a template matching technique to automatically detect a polyp in a CT image of a bowel;

25 FIG. 8 is a flow diagram showing the steps of a rolling ball technique to automatically detect a polyp in a CT image of a bowel; and

FIGs. 8A-8H are examples of automatic polyp detection in a CT image of a bowel using the rolling ball technique;

FIG. 8I is an example of automatic polyp detection using the rolling ball technique in a three dimensional image;

5 FIG. 9 is a flow diagram showing the steps of a distance matching technique to automatically detect a structure in a CT image of a bowel; and

10 FIGs. 9A-9G are examples of automatic polyp detection in a CT image of a bowel using the distance matching technique.

#### DESCRIPTION OF THE PREFERRED EMBODIMENTS

Before describing a virtual colonoscopy system which includes a digital bowel subtraction processor (DBSP) and / or automated polyp detection processor (APDP) and the operations performed to digital cleanse a bowel and automatically detect a polyp, some introductory concepts and terminology are explained.

A computed tomography (CT) system generates signals which can be stored as a matrix of digital values in a storage device of a computer or other digital processing device. As described herein, the CT image is divided into a two-dimensional array of pixels, each represented by a digital word. One of ordinary skill in the art will recognize that the techniques described herein are applicable to various sizes and shapes of arrays. The two-dimensional array of pixels can be combined to form a three-dimensional array of pixels. The value of each digital word corresponds to the intensity of the image at that pixel. Techniques for displaying images represented in such a fashion, as well as techniques for passing such images from one processor to another, are known.

25 As also described herein, the matrix of digital data values are generally referred to as a “digital image” or more simply an “image” and may be stored in a digital data storage device, such as a memory for example, as an array of numbers representing the spatial distribution of energy at different wavelengths in a scene.

Each of the numbers in the array correspond to a digital word typically referred to as a "picture element" or a "pixel" or as "image data." The image may be divided into a two dimensional array of pixels with each of the pixels represented by a digital word. Thus, a pixel represents a single sample which is located at specific spatial coordinates in the image.

5

It should be appreciated that the digital word is comprised of a certain number of bits and that the techniques of the present invention can be used on digital words having any number of bits. For example, the digital word may be provided as an eight-bit binary value, a twelve bit binary value, a sixteen bit binary value, a thirty-two bit binary value, a sixty-four bit binary value or as a binary value having any other number of bits.

Reference is also sometimes made herein to an image as a two-dimensional pixel array. An example of an array size is size 512 x 512. One of ordinary skill in the art will of course recognize that the techniques described herein are applicable to various sizes and shapes of pixel arrays including irregularly shaped pixel arrays.

5

An "image region" or more simply a "region" is a portion of an image. For example, if an image is provided as a 32 X 32 pixel array, a region may correspond to a 4 X 4 portion of the 32 X 32 pixel array.

10 In many instances, groups of pixels in an image are selected for simultaneous consideration. One such selection technique is called a "map" or a "local window." For example, if a 3 X 3 subarray of pixels is to be considered, that group is said to be in a 3 X 3 local window. One of ordinary skill in the art will of course recognize that the techniques described herein are applicable to various sizes and shapes of local windows including irregularly shaped windows.

110

It is often necessary to process every such group of pixels which can be formed from an image. In those instances, the local window is thought of as "sliding" across the image because the local window is placed above one pixel, then moves and is placed above another pixel, and then another, and so on. Sometime the "sliding" is made in a raster pattern. It should be noted, though, that other patterns can also be used.

25

It should also be appreciated that although the detection techniques described herein are described in the context of detecting polyps in a colon, those of ordinary skill in the art should appreciate that the detection techniques can also be used search for and detect structures other than polyps and that the techniques may find application in regions of the body other than the bowel or colon.

30

Referring now to FIG. 1, a system for performing virtual colonoscopy 10 includes a computed tomography (CT) imaging system 12 having a database 14 coupled thereto. As is known, the CT system 10 produces two-dimensional images of cross-sections of regions of the

human body by measuring attenuation of X-rays through a cross-section of the body. The images are stored as digital images in the image database 14. A series of such two-dimensional images can be combined using known techniques to provide a three-dimensional image of the colon. A user interface 16 allows a user to operate the CT system and also allows the user to access and view the images stored in the image database.

5 A digital bowel subtraction processor (DBSP) 18 is coupled to the image database 14 and the user interface 16. The DBSP receives image data from the image database and processes the image data to digitally remove the contents of the bowel from the digital image. The DBSP can 10 then store the image back into the image database 14. The particular manner in which the DBSP processes the images to subtract or remove the bowel contents from the image will be described in detail below in conjunction with Figs. 2-6. Suffice it here to say that since the DBSP digitally subtracts or otherwise removes the contents of the bowel from the image provided to the DBSP, the patient undergoing the virtual colonoscopy need not purge the bowel in the conventional manner which is known to be unpleasant to the patient.

20 The DBSP 18 may operate in one of at least two modes. The first mode is referred to a raster mode in which the DBSP utilizes a map or window which is moved in a predetermined pattern across an image. In a preferred embodiment, the pattern corresponds to a raster pattern. The window scans the entire image while threshold values are applied to pixels within the image in a predetermined logic sequence. The threshold process assesses whether absolute threshold values have been crossed and the rate at which they have been crossed. The raster scan approach looks primarily for "air" pixels proximate (including adjacent to) bowel pixels. The processor 25 examines each of the pixels to locate native un-enhanced soft tissue. As a boundary between soft tissue (e.g. bowel wall) and bowel contents is established, pixels are reset to predetermined values depending upon which side of the boundary on which they appear.

30 The second mode of operation for the DBSP 18 is the so-called gradient processor mode. In the gradient processor mode, a soft tissue threshold (ST) value, an air threshold (AT) value and a bowel threshold (BT) value are selected. A first mask is applied to the image and all pixels

having values greater than the bowel threshold value are marked. Next, a gradient is applied to the pixels in the images to identify pixels in the image which should have air values and bowel values. The gradient function identifies regions having rapidly changing pixel values. From experience, one can select bowel/air and soft tissue/air transition regions in an image by 5 appropriate selection of the gradient threshold. The gradient process uses a second mask to capture a first shoulder region in a transition region after each of the pixels having values greater than the BT value have been marked.

Once the DBSP 18 removes the bowel contents from the image, there exists a relatively 10 sharp boundary and gradient when moving from the edge of the bowel wall to the "air" of the bowel lumen. This is because the subtraction process results in all of the subtracted bowel contents having the same air pixel values. Thus, after the subtraction, there is a sharp boundary and gradient when moving from the edge of the bowel wall to the "air" of the bowel lumen. In this context, "air" refers to the value of the image pixels which been reset to a value corresponding to air density. If left as is, this sharp boundary (and gradient) end up inhibiting the 3D endoluminal evaluation of the colon model since sharp edges appear as bright reflectors in the model and thus are visually distracting.

A mucosa insertion processor 19 is used to further process the sharp boundary to lesson the impact of or remove the visually distracting regions. The sharp edges are located by applying a gradient operator to the image from which the bowel contents have been extracted. The gradient operator may be similar to the gradient operator used to find the boundary regions in the gradient subtractor approach described herein. The gradient threshold used in this case, however, typically differs from that used to establish a boundary between bowel contents and a bowel wall.

25 The particular gradient threshold to use can be empirically determined. Such empirical selection may be accomplished, for example, by visually inspecting the results of gradient selection on a set of images detected under similar scanning and bowel preparation techniques and adjusting gradient thresholds manually to obtain the appropriate gradient (tissue transition selector) result.

The sharp edges end up having the highest gradients in the subtracted image. A constrained gaussian filter is then applied to these boundary (edge) pixels in order to "smooth" the edge. The constraint is that the smoothing is allowed to take place only over a predetermined width along the boundary. The predetermined width should be selected such that the smoothing process does not obscure any polyp or other bowel structures of possible interest. In one embodiment the predetermined width corresponds to a width of less than ten pixels. In a preferred embodiment, the predetermined width corresponds to a width in the range of two to five pixels and in a most preferred embodiment, the width corresponds to a width of three pixels. The result looks substantially similar and in some cases indistinguishable from the natural mucosa seen in untouched bowel wall, and permits an endoluminal evaluation of the subtracted images.

Also coupled between the image database 14 and the user interface 16 is an automated polyp detection processor (APDP) 20. The APDP 20 receives image data from the image database and processes the image data to detect and /or identify polyps, tumors, inflammatory processes, or other irregularities in the anatomy of the colon. The APDP 20 can thus pre-screen each image in the database 14 such that an examiner (e.g. a doctor) need not examine every image but rather can focus attention on a subset of the images possibly having polyps or other irregularities. Since the CT system 10 generates a relatively large number of images for each patient undergoing the virtual colonoscopy, the examiner is allowed more time to focus on those images in which the examiner is most likely to detect a polyp or other irregularity in the colon. The particular manner in which the APDP 20 processes the images to detect and /or identify polyps in the images will be described in detail below in conjunction with Figs. 7-9. Suffice it here to say that the APDP 20 can be used to process two-dimensional or three-dimensional images of the colon. It should also be noted that APDP 20 can process images which have been generated using either conventional virtual colonoscopy techniques (e.g. techniques in which the patient purges the bowel prior to the CT scan) or the APDP 20 can process images in which the bowel contents have been digitally subtracted (e.g. images which have been generated by DBSP 18).

It should also be appreciated that polyp detection system 20 can provide results generated thereby to an indicator system which can be used to annotate (e.g. by addition of a marker, icon

or other means) or otherwise identify regions of interest in an image (e.g. by drawing a line around the region in the image, or changing the color of the region in the image) which has been processed by the detection system 20.

5 Referring now to FIGS. 1A – 1D in which like elements are provided having like reference designations throughout the several views, a series of images 19a-19d illustrating a bowel before (Figs. 1A, 1B) and after (Figs. 1C, 1D) processing via the DBSP 18 (Fig. 1) are shown.

10 In Fig. 1A, the image 19a corresponds to a single slice of a CT scan. The image 19a includes a plurality of opacified bowel contents 20 (shown as light colored regions) and regions of air 22 (shown as dark colored regions). The image 19a also includes regions 24 which correspond to native soft tissue and regions 26 which correspond to portions of a bowel wall.

Image 19b (Fig. 1B) is three-dimensional view of the colon formed from a series of single slice CT scans. The opacified bowel contents 20 are shown. The opacified bowel contents 20 impairing the view of the bowel wall and thus limit the ability to detect regions of interest along the bowel wall.

15 In Fig. 1C, single slice CT scan image 19c is the same as image 19a except that the bowel contents present in the image 19a (Fig. 19A) have been digitally subtracted from the image 19a. The image 19c does not include the opacified bowel contents present in Fig. 19A. Rather the bowel contents 20 (Fig. 19A) have been replaced by regions 22 (shown as dark colored regions) corresponding to air. The image 19c also includes the native soft tissue and bowel wall regions 24, 26 respectively.

20 As discussed above, the DBSP 18 receives an image of a section of a bowel and digitally subtracts the contents 20 of the bowel section. Here the operation is performed on a two-dimensional image and a series of such two-dimensional images (each of which has been processed by the DBSP 18) can be combined to provide a three-dimensional image of the bowel section. Such two-dimensional and three-dimensional images can then be processed via the

APDP 20 (Fig. 1) to detect polyps, tumors, inflammatory processes, or other irregularities in the anatomy of the colon.

FIGs. 2-9 are a series of flow diagrams showing the processing performed by a processing apparatus which may, for example, be provided as part of a virtual colonoscopy system 10 such as that described above in conjunction with FIG. 1 to perform digital bowel subtraction and automated polyp detection. The rectangular elements (typified by element 30 in FIG. 2), herein denoted "processing blocks," represent computer software instructions or groups of instructions. The diamond shaped elements (typified by element 64 in FIG. 5), herein denoted "decision blocks," represent computer software instructions, or groups of instructions which affect the execution of the computer software instructions represented by the processing blocks.

Alternatively, the processing and decision blocks represent steps performed by functionally equivalent circuits such as a digital signal processor circuit or an application specific integrated circuit (ASIC). The flow diagrams do not depict the syntax of any particular programming language. Rather, the flow diagrams illustrate the functional information one of ordinary skill in the art requires to fabricate circuits or to generate computer software to perform the processing required of the particular apparatus. It should be noted that many routine program elements, such as initialization of loops and variables and the use of temporary variables are not shown. It will be appreciated by those of ordinary skill in the art that unless otherwise indicated herein, the particular sequence of steps described is illustrative only and can be varied without departing from the spirit of the invention.

Turning now to FIG. 2, the steps in a virtual colonoscopy are shown. As shown in step 25 30, the virtual colonoscopy process begins by placing a contract agent in the region of the colon in which the CT scan will be performed. Typically, the patient ingests the contrast agent. It should be appreciated however, that any technique for placing the contrast agent in the bowel may also be used. The contrast agent may be taken in small amounts with meals beginning approximately 48 hours or so prior to a scheduled CT exam. The contrast agent can be of any of 30 the commercially available types such as Gastrograffin, Barium or Oxilan, for example.

Next, as shown in step 32, the CT exam takes place and images of a body region (e.g. an entire abdomen) are generated as shown in step 34.

5 The image data is then sent to an analysis system and analyzed as shown in step 36. One or more images are selected for analysis (can be a single slice or a series of slices). This can be accomplished using commercially available systems such as the Vitrea System available through Vital Images, Inc. Minneapolis, MN.

10 Then, as shown in step 38, the contents of the bowel are digitally subtracted from the CT images. The digital subtraction step can be performed using either of the techniques described below in conjunction with FIGs. 3 and 5 below.

After the digital subtraction step, the results of the bowel images having the contents thereof digitally removed are displayed as shown in step 40.

Referring now to FIG. 3, a first technique for digitally subtracting the contents of a bowel utilizes functions from the so-called “toolbox” found in the MATLAB computer program (available through The Math Works, Natick, Massachusetts). This technique begins by applying a threshold function to the image data and selecting all image elements above the threshold.

Next as shown in step 44, a gradient is applied to the original image to identify “shoulder regions.” Once the shoulder regions are identified, an image dilation step is performed on the shoulder region (i.e. an expansion is performed on selected pixels in the shoulder region). The 25 gradient functions can be provided as any number of functions including but not limited to the Roberts or Sobel gradient functions. Generally, in those regions in which the air water interfaces are horizontal, it is desirable to use a horizontal gradient.

Next, as shown in step 46, the bowel contents are digitally subtracted based on the gradient analysis. Thus, after selecting and dilating the gradient, the subtraction of the bowel contents is performed. Mathematically this can be represented as:

$$5 \quad \text{Subtracted Image Values} \approx \text{Original Image Values} - (\text{Threshold Values} + \text{Gradient Values})$$

in which :

10  $\text{Original Image Values} =$  the values of the digital image as measured by the CT System and massaged as necessary but prior to DBS processing

$\text{Threshold Values} =$  a selected threshold value

$\text{Gradient Values} =$  values resultant from the selected gradient function

Referring briefly to FIGs. 4 – 4C, an image of a bowel portion 49 (Fig. 4) includes an unopacified region 50 (Fig. 4), and an opacified region 53 (Fig. 4) and a volume averaging region comprised of sections 51, 52 (Fig. 4). The contrast agent ingested increases the contrast between the bowel contents (represented by opacified region 53) and air (represented by the unopacified region 50). The regions 51, 52 correspond to a boundary area between the unopacified region 53 and the opacified region 53. That is, a clearly defined boundary does not exist between the unopacified and opacified regions 49, 53.

25 Referring now to FIG. 4A, a plot 55 of pixel values in Hounsfield Units (HU) vs. pixel locations in a CT image reveals a first region 55a corresponding to a soft tissue region, a second region 55b corresponding to an opacified bowel contents region and a third region 55c corresponding to an air region. A transition region thus exists between the soft tissue region 55a and the air region 55c. A gradient function applied to curve 55 produces boundary 57 shown in Fig. 4B. Thus, as shown in Fig. 4B, after application of a gradient function, and subtraction, a

relatively sharp transition 57a exists between regions 55a and 55c. It is this transition on which the mucosal insertion processor 19 operates as described above in conjunction with Fig. 1.

As shown in Fig. 4C, after application of the mucosal insertion process, a transition 57a

5 between the soft tissue region 55a and the air region 55c is provided.

Referring now to FIG. 5, a second technique for digitally subtracting the contents of a bowel includes the step of generating a pixel analysis map (PAM) from the image as show in step 60. In one particular embodiment, the image is provided as a 512 X 512 image and the PAM is 10 provided as a 7 X 8 matrix generated from the image.

The PAM is moved across the image in a raster pattern. As the PAM is moved from location to location across the different regions of the image, steps 62-79 are performed. As shown in step 62, the central elements (upper left (ul), upper right (ur) lower left (ll), lower right (lr) shown in Fig. 5A) of the PAM are the focused of the analysis. Steps 64 and 66 implement a loop in which a search is performed until an air region is found.

Once the air region is found, processing proceeds to step 68 where the area around the air element is searched to locate a bowel region as shown in step 70. If the region corresponds to a bowel region, then processing proceeds to step 74 where it is determined if the bowel region is adjacent to an air region. If the bowel region is adjacent to the air region, then the bowel contents are subtracted as shown in step 76.

If in step 70 a decision is made that the selected PAM does not correspond to bowel, then

25 steps 77 and 78 implement a loop in which a new PAM is selected until a bowel region is found.

This process is repeated for each of the ul, ur, ll, lr in the local window during the raster pattern scan.

Referring to Figs. 5A-5C in which like element are provided having like reference designations throughout the several views, a 512 X 512 image 80 of the type generated by a CT system for example, is shown having a 7 x 8 local window 82 disposed thereover. The local window 82 is moved across the image in a raster pattern designated as reference numeral 84. The image 80 is that of a two-dimensional section of a bowel 86. Portions of the bowel 86 have contents 88a (indicated by cross-hatching) and portions 88b correspond to air. The bowel 86 has a fold 89 therein and a plurality of polyps 90a – 90b.

As may be more clearly seen in Fig. 5B, in which like elements in Fig. 5A are shown having like reference designations, polyp 90b is obscured by the bowel contents 88a and thus may be difficult to see in an image generated by a CT scan. In particular, such a polyp may be particularly difficult to see in a three-dimensional (3D) view. After the digital subtraction process of the present invention, the image shown in FIG. 5C results. In FIG. 5C, the bowel contents have been removed and the polyp 90b is clearly visible. Thus, when a visual examination of the CT image is conducted, the polyp 90b is exposed and can be easily viewed.

Referring now to Fig. 5D, a pixel analysis map (PAM) 82' includes four central elements 90a-90. As described above, axial digital bowel cleansing can be performed using a marching squares routine to scan through selected regions of an image (e.g. image 80 in Fig. 5A) to reset pixels that fall above a bowel threshold value. The bowel threshold value may be set by the user. One technique uses an air threshold and a soft tissue threshold (both of which are expressed in Hounsfield units) to also segment the bowel mucosal boundary, for use in polyp detection. Segmented pixels (the bowel boundary) are set to a value of 2500.

In the technique, the central four elements 91a-91d of the PAM 82' are used as the marching square. An examination of the image to which the PAM 82' is applied is made by looking out to the far boundaries created by the "L" and "R" level pixels. It should be noted that in Fig. 5D, an "o" designates boundary pixels while an "x" designates outer boundary pixels.

In the technique one of the central pixels is selected (e.g. ul 91a) and one direction is

selected (e.g. the SE direction designated by reference line 92. Next, the furthest point away in that direction is examined. In this example, the furthest point corresponds to the point designated SE is selected.

5        The difference between the value of the ul pixel 91a and the value of the pixel at the location SE is computed. If the difference between the values of the SE and ul is large enough, then one can conclude that a substantial threshold exists. Then points which are closer to the ul pixel than the SE pixel are examined (e.g. pixels at the IL and Ll locations). This process is then 10 repeated for each direction. Once all the directions have been tested, then a new central pixel is selected (e.g. one of pixels 91b-91d) and the process is repeated.

Referring now to FIG.6, the process of searching around the pixel ul in the local window begins with steps 100 and 102 in which a PAM and one of the elements ul, ur, ll, lr are selected. In the example discussed in FIG. 6, the pixel in location ul is selected as shown in step 102. Thus the processing starts at pixel ul and each of the neighbors to ul (e.g. ur, ll, lr) are examined. It should be appreciated, however, that the process could also start one of the other pixels (i.e. ur, ll, lr) and then the corresponding neighbors would be examined.

Considering first neighbor ur, decision is made as to whether ur is above the bowel threshold as shown in step 106. This process is explained further in conjunction with FIG. 6A. If the value of ur is above the bowel threshold, then processing flows to step 108 in which the pixel value is subtracted to reset the value to the air value. Processing then proceed to step 114 in which the next neighboring pixel is examined.

25        If in step 106 it is determined that the value of ur is not above the bowel threshold, then a determination is made as to if any more pixel exist to the right of ur as shown in step 110. If such pixels do exist then the system looks one pixel further to the right and processing returns to step 106. If no such pixels exist, then processing proceeds to again to step 114.

30        The above steps are repeated for each of the pixels ul, ll, lr as indicated in step 116.

Referring now to FIGs. 6A and 6B, the threshold process is illustrated. There are two parts to the threshold process. The first part is to determine the air-bowel boundary. The second part requires a decision as to how to treat shoulder region 120.

5

If the difference between the extreme neighbor uE and the close neighbor P1 is above a gradient threshold, then use that as well as an indication of the air-bowel interface and all values between the starting pixel (i.e. uL in the present example) and the far extreme pixel (i.e. uE in the present example and which is the bowel boundary) are reset to air values. That is, the values for 10 pixels P1, P2 are reset to provide the boundary 122 shown in FIG. 6B. The resultant pixel values (i.e. the reset values for pixels P1, P2) are the values upon which the subtraction is based. The pixel values are preferably set in this way since it is computationally efficient to trigger with the smallest number and because the smallest polyps of interest are bigger than a two pixel distance and the shoulder region is only 1-2 pixels in length. Thus, the direction in which to move the boundary is selected for computationally efficiency.

127  
128  
129  
130

A second possibility for resetting the pixel values is illustrated by the dashed line 122' in FIG. 6B. In this case, the values of pixels P1, P2 are set to bowel values.

Although the above DBS processes have been described in conjunction with two-dimensional images, it should be appreciated that the same concepts apply equally well to three-dimensional images. That is the concepts can be applied along any axis of an image.

Referring now to FIG. 7, a process for automated polyp detection is described. It should 25 be noted that prior to the processing performed in conjunction with FIG. 7, a polyp template is formed. The polyp template is formed by obtaining a CT image which includes a polyp and excising the polyp from the image. That excised polyp image is then used as the template. Alternatively, one can empirically generate a family of templates that resemble the known morphology and density of polyps (or other structure sought to be detected).

30

Processing begins with the step 130 in which an image portion is selected. Processing then proceeds to step 132 in which a polyp identification function is applied to the selected image portion. Next, in step 134, a correlation is performed between the output of the identification function and the image.

5

The correlation is performed as:

$$[\text{Correlation Matrix}] = 2\text{d inverse Fourier Transform of } [2\text{d inverse Fourier Transform}(T)$$

$$*2\text{d inverse Fourier Transform}(I)]$$

10

in which:

T = the polyp template; and

I = the image.

30

It should be appreciated that the template matching technique can also be performed by taking a spherical template and applying the spherical template to voxels (i.e. 3D picture elements) formed from a series of two-dimensional images by interpolating values between the images as is known. Also, the original template must be transposed to form an operational molecule. The operational molecule is the template rotated 180 degrees used as a temporary computational transform of the template for the purposes of identifying regions of similarity between the template and the image corresponding to the search for polyps within the image.

It should be noted that if the template is formed from a polyp of a certain size, then the template must be scaled to detect polyps of different sizes. This can be done by utilizing a four-dimensional process in which the fourth dimension is a scaling of the polyp template. It should also be noted that it may be necessary to modify the polyp template to detect polyps having shapes which are different from spheres.

Referring now to FIG. 8, a second process for automatic detection of polyps, referred to as the so-called “rolling ball” technique begins with the step of segmenting the image as shown in

step 136. In this step all of the image information is taken and certain portions of the image are extracted for use in the analysis. A conventional techniques including but not limited to the so-called "marching cubes" technique can be used in the segmentation step. It should be appreciated that the segmentation step and all of the steps show in FIG. 8 can be performed on images which have been cleansed using the above-described DBSP process. Alternatively, the segmentation step and all of the steps show in FIG. 8 can be performed on images provided using conventional techniques (e.g. images which have not been cleansed using the DBSP technique).

5 Next as show in step 138, a virtual ball is rolled along the bowel boundary. When the ball is rolled around the perimeter, the system detects changes in direction of the ball to identify 10 polyps as shown in step 140. In general, the process of classifying the features of the bowel are accomplished by marking three points where turns exist. The points are selected by looking at the changes in slope (e.g. the derivative). Next the distances between the marked points are computed and the ratios between the distances are used to identify bowel features or characteristics of the bowel. The features of the bowel perimeter are thus classified based upon the path of the ball and an advance knowledge of the geometric characteristic of the polyp or other irregularity being detected is therefore required.

15 20 25 30

An example of the rolling ball polyp detection technique is shown in Figs. 8A-8G. Referring first to Fig. 8A, an image 142 includes several regions 143a – 143f. As shown in Fig. 8B, region includes a features 150 and 152. A rolling ball polyp detection process is first performed on feature 150 as shown in Fig. 8C.

25 As shown in Fig. 8C, a test element 154 having the shape of circle (or ball) is moved or rolled along a surface 156 which may correspond for example to the surface of a bowel wall. In this example, the ball moves in the lumen region 155. It should be appreciated, however, that in alternate embodiments, the test element 154 may be provided having a shape other than a circular shape. It should also be appreciated that in some embodiments it may be desirable to move the ball 154 in a region other than the lumen region 155. When the ball 154 reaches a section of the 30 surface 156 at a location where two portions of the ball 154 contact two portions of the of the

surface 156 then a first point 158 is marked. Point 158a corresponds to the point where the slope of the surface 156 changes sign.

After point 158a is marked then the ball continues its path and points 158b, 158c are marked. Thus three points are marked where turns exist. Each of the points 158a – 158c are selected by looking at the changes in slope (e.g. the derivative). Next the distances between the marked points are computed. Here the distance between points 158a and 158b is designated as 159a, the distance between points 158b and 158c is designated as 159b and the distance between points 158a and 158c is designated as 159c. The ratios between the distances 159a – 159c are then used to identify bowel features or characteristics of the bowel. In Fig. 8C, the ratio is computed as follows: the sum of the lengths 159a and 159b divided by the length 153c. The ratio of the lengths 159a – 159c along the path defined by points 158a – 158c indicate that the structure 152 has the shape of a polyp. This can be accomplished by comparing the ratio value to a predetermined threshold value. Thus, the above techniques computes the ratio formed by the deflection and travel paths of the test element and uses this information (e.g. by comparing the ratio value to a threshold value) to characterize the bowel structure.

As shown in Fig. 8D, the point 158 is defined by the intersection of lines 159a, 159b. Each of lines 159a, 159b project from the center of the ball 154 to the point at which the respective surfaces of the ball contact the two points of the surface 156.

It should be noted that it is important to distinguish collision points (e.g. points 158a, 158c) from turnaround points (e.g. point 158b).

Referring now to Fig. 8E, a semi-circular shaped structure 153 exists on the side of a triangular shaped structure 152. It should be appreciated that in this case, there are two ratios to compute. One ratio value for the structure 152 (i.e. the structure having the triangular shape) is formed by the sum of the lengths 161a – 161e divided by the length 161f. Another ratio value for the semi-circular shaped structure 153 is formed by the sum of the lengths 161c – 161c divided by the length 161g.

Referring now to Figs. 8F – 8H, surface 159 forms a structure 160. The rolling ball technique is used to define three points 162a, 162b, 162c which define the structure 160. In Fig. 8F, an average center point 164 has been computed (e.g. via the segmentation technique) and can 5 be used to provide sufficient information with respect to “turning in” versus “turning away.” This is accomplished by evaluating the absolute value of slope from collision to collision slope (referred to hereinafter as the pre-slope). The absolute value of the preslope will change as the ball test point moves around the bowel circumference. When a collision is found, the preslope value is used to assess the turn around point(s) and returns to the bowel wall. Turn around points 10 correspond to maxima and minima of the slope encountered by the ball center point as this point moves from wall collision to wall collision.

TOP SECRET 05423680

A collision can be defined as when the perimeter of the test ball contacts two portions of the wall as illustrated in Fig. 8D. By setting the perimeter of ball correctly – as determined by empirical evaluation - one can select feature changes of a polyp or fold from the background concavity of the bowel perimeter.

It should be appreciated that the rolling ball technique can also be performed in three dimensions (i.e. both around a circumference and up and down a longitudinal axis of a short tube) as shown in FIG. 8I. In Fig. 8I, a series of axial slices 165a – 165c are used to construct a three-dimensional image of bowel sections 166 (small bowel loop) and 167 (loop of bowel). Regions 168a – 168e correspond to the portions of the bowel which would be present in the axial images (e.g. as shown in Figs. 1A and 1C). In the case where the rolling ball technique is applied to a 25 three-dimensional bowel image, care must be taken to insure that each region of the bowel “tube” is examined.

Referring now to Fig. 9, a third process for automatic detection of polyps, referred to as the so-called “distance search” technique begins with the step of selecting a polyp template 170. The template is selected having a predetermined shape. The shape is preferably selected to 30 correspond to the shape of the bowel anomaly.

Referring briefly to FIG. 9A, for example, a template 180 includes a local window boundary 182 and a template pattern 184. The template pattern is here selected to be a circle 184 since the polyps tend to have substantially circular shapes as seen in 2D images. If applied in 3D, 5 then spherical, or semi-sphere or other forms could be used by utilizing a 3D implementation. It should, however, be appreciated that in those applications in which the lesion sought to be detected had other than a circular shape, the template pattern would be selected accordingly. For example, if the lesion sought to be detected had a substantially triangular shape, then the template pattern would also be selected having a substantially triangular shape. The side 180a of the local 10 window 180 is selected having a length which is as large as the largest lesion to be detected. The template pattern 184 is selected having a dimension as small as the smallest lesion to be detected.

200 195 190 185 180 175 170 165 160 155 150 145 140 135 130 125 120 115 110 105 100 95 90 85 80 75 70 65 60 55 50 45 40 35 30 25 20 15 10 5

Referring again to FIG. 9, once the window size and template pattern and size are selected, the local window 182 is scanned across the image of the bowel perimeter once it has already been segmented. Next, as shown in step 174 in FIG. 9, the distances between points on the template 184 and the perimeter points within the window 182 are made.

This may be more clearly understood with reference to FIGs. 9B – 9D, in which an image 186 is segmented to include only the bowel perimeter 188. The bowel perimeter includes a fold 190 and a lesion 192. The window 182 is placed over the image 186 and moved across the entire image 186. When the window 182 reaches a location in the image 186 in which a portion of the bowel boundary is within the window and within the template 184 (as shown in FIGs. 9C, 9D) the 25 distance between the points on the template 184 and the perimeter points within the window 182 are made. In one embodiment, the distances between 10-30 test points on the unit test circle and boundary points present within the moving frame should initially be made. Those of ordinary skill in the art should appreciate of course that the precise number of points used is not critical and that in some applications, it may be desirable or necessary to use a number of points fewer than 10 or greater than 30.

Referring now to step 176 and FIG. 9E, a determination is made as to whether the distances are equal. When the test circle becomes centered within a circular lesion, then the distances between the circle perimeter and boundary points of the lesion becomes equal and the standard deviation of a group of those distances approaches a minimum value (See Figs. 9F and 5 9G). It should be noted that the above process is carried out in one plane and it is necessary to search in three orthogonal planes to be complete. The point where the standard deviation of a group of those distances approaches a minimum value is the point which should be marked as a center of a suspected lesion (i.e. identified as a region of interest as indicated in step 178). After the technique is run in all three planes, those lesions that were tagged in 2 of 3 or 3 of 3 planes 10 can be finally tagged as suspicious regions. This technique can thus be used to distinguish a fold from a polyp. It should be noted that depending upon the feature to be selected, other statistical tools, aside from standard deviation can be used to identify regions of match between the roving template and features of the segmented image.

The technique described above in conjunction with FIGs. 9-9G, thus searches for patterns of distance. The technique is thus relatively computationally expensive but it is also relatively rigorous. One advantage of this technique is that it does not matter how large the template is relative to the polyp so one scanning works for all lesions.

In Fig. 9G, a plot 209 of distance around the template vs. template position is shown. Region 210 of curve 209 is relatively flat thus indicating that a region of the image contained a shape which matched the shape of the template. When the template is provided having a round shape (e.g. as shown in Figs. 9E, 9F), the flat region 210 indicates that a corresponding shape is found in the structure being searched.
